

Staggered liquid phases of the 1D Kondo-Heisenberg lattice model

Oron Zachar

ICTP, 11 strada Costiera, Trieste 34100, Italia

(February 1, 2008)

We introduce a new family of one dimensional liquids, which we label as "Staggered-Liquids", in the phase diagram of the 1D Kondo-Heisenberg model. It encompasses three distinct spin gapped liquids and a new Luttinger liquid phase. A Staggered Liquid is characterized by gapless modes with "large fermi-sea" signature in the charge density wave (CDW) mode, and in that the superconducting order involves the near condensation of charge-2e Cooper pairs with finite center of mass momentum. In particular, the conventional gapless $2k_F$ CDW and $k = 0$ pairing modes are absent. In the process, we analytically derive the phase transition from an intermediate coupling spin gap phase to the strong coupling gapless LL phase of the Kondo-Heisenberg lattice model.

I. INTRODUCTION

Multicomponent one dimensional electronic systems, of which the one dimensional Kondo-Heisenberg (K-H) model is a particular example, exhibit new phases that were unanticipated in the earlier studies of the one dimensional electron gas (1DEG). The one dimensional Kondo-Heisenberg model consists of a 1DEG interacting with a Heisenberg spin- $\frac{1}{2}$ chain via spin exchange interaction. In the present paper we characterize the stable fixed points of this model.

In particular limits of parameters, we obtain well controlled analytical solutions which enable us to enumerate and characterize the quantum numbers of *all* gapless modes. Gapless modes are properties of the fixed point. Thus, our analysis lists the *minimal set of stable fixed points in the global phase diagram* of the Kondo-Heisenberg model. Surprisingly, we find that there is a common feature to all the fixed points in that CDW and pairing gapless modes are obtained with "unusual" wave numbers, and hence give the label "staggered liquids" to the family of fixed points. In particular, whereas previously catalogued liquid phases of the 1DEG have a gapless charge $2e$ pairing mode at $k = 0$, in a Staggered Liquid this mode appears at non-zero wave-vector. Put differently, in a Staggered Liquid phase the dominant superconducting order involves the near condensation of Cooper pairs with finite center of mass momentum. Similarly, there is no gapless CDW mode at wavenumber $2k_F$. Our results are summarized in tables-1,2 of section-II.

In previous publications [1,2], we have already characterized two distinct spin gap phases (at weak coupling [2] and at a "Toulouse point" value of parameters). In the present paper we add a new gapless Luttinger liquid (LL) phase (labeled "Staggered LL") which is obtained by going away from the Toulouse point towards stronger coupling. Interestingly, though its mathematical form is similar to commensurate-incommensurate transition, we find the phase transition is *first order*. To our knowledge, it is the first analytic derivation of the phase transition from an intermediate coupling spin gap phase to the strong coupling gapless LL phase in the Kondo lattice model. Moreover, a third distinct spin gap phase is ob-

tained by introducing weak attractive interactions to the staggered LL (and hence we name it "staggered BCS").

We emphasize that in this paper we limit ourselves to cataloguing the stable fixed points. We do not discuss the range of their basins of attraction and the validity of the solutions away from the quantitatively controlled limits of parameters. In other words, we defer to a future publication the discussion of how exactly to construct the phase diagram as a function of Kondo interaction strength for a given discrete Kondo-Heisenberg lattice model at given incommensurate filling and with spin rotation invariance.

The paper is organized as follows: In section-II, we define the model and the order parameters. Our results are summarized in tables-1,2. (The derivation of these results is presented in the ensuing sections). In section-III, we review the weak coupling limit ($J_K \ll J_H$) spin gap fixed point solution [2]. In section-IV, we review the Toulouse limit ($J_H \ll J_K \sim E_F$) spin gap fixed point solution, with some extended discussion of the Unitary transformation. In section-V, we derive the phase transition to a gapless LL away from the Toulouse point towards stronger coupling ($J_H \ll E_F \ll J_K$). In section-VI we make some additional concluding remarks. In order to facilitate the reading of the paper, a discussion and bosonization representation of order parameters is given in an Appendix.

II. KONDO-HEISENBERG MODEL AND ITS ZERO TEMPERATURE FIXED POINTS

A. The model

The Kondo-Heisenberg model (1) consists of two *inequivalent* interacting chains; one is a one-dimensional electron gas (described by the Hamiltonian H^{1DEG} [5]), and the other an antiferromagnetic Heisenberg chain of localized spins $1/2$, $\{\vec{\tau}_j\}$. The chains interact via a spin exchange interaction with an antiferromagnetic coupling constant $J_K > 0$.

$$H = H^{1DEG} + H^{Heis} + H_K \quad (1)$$

$$H^{Heis} = J_H \sum_j \vec{\tau}_j \cdot \vec{\tau}_{j+1} \quad (2)$$

$$H_K = 2J_K \sum_j \vec{\tau}_j \cdot \vec{s}(x_j) \quad (3)$$

where $\vec{s}(x_j) = \psi_\alpha^\dagger(x_j) \frac{\vec{\sigma}_{\alpha\beta}}{2} \psi_\beta(x_j)$ is the electron gas spin density operator at position x_j of the local spin $\vec{\tau}_j$ of the Heisenberg chain. We focus on the low energy and long-distance behavior of the electron's correlation functions by taking the continuum limit of the electron gas and linearizing the 1DEG dispersion relation about the fermi points, $\pm k_F$, with corresponding right and left going electron fields, R_σ and L_σ ;

$$\psi_\sigma(x) = R_\sigma(x)e^{+ik_F x} + L_\sigma(x)e^{-ik_F x},$$

Where $\sigma = \uparrow, \downarrow$.

FIG. 1. Kondo-Heisenberg model

The effective Fermi wave numbers (in the sense of the generalized Luttinger's theorem [3]) for the 1DEG and the spin chain are $2k_F$ and $2k_F^{Heis} = \pi/b$ respectively (where $b = x_{j+1} - x_j$ is the distance between the local spins of the Heisenberg chain). It is assumed that the two systems are mutually incommensurate, and that $2k_F$ is incommensurate with any underlying ionic lattice. The continuum limit is taken for the 1DEG while the Heisenberg chain is initially left discrete (and remain so in some of the limit solutions derivations). Therefore, *the totality of our analysis is rigorously valid in the limit $2k_F \gg \pi/b$* (i.e., the number of electrons is much larger than the number of local spin- $\frac{1}{2}$ moments per unit length).

The 1DEG spin currents are decomposed into forward and back-scattering parts;

$$\begin{aligned} \mathbf{s}(x) &= \psi_\alpha^\dagger(x_j) \frac{\vec{\sigma}_{\alpha\beta}}{2} \psi_\beta(x_j) \\ &= \vec{J}_s(x) + \vec{n}_s(x) \end{aligned}$$

where $\vec{J}_s(x) = \vec{J}_{sR}(x) + \vec{J}_{sL}(x)$, $\vec{J}_{sR} = \frac{1}{2}R_\sigma^\dagger \vec{\sigma}_{\sigma\sigma'} R_{\sigma'}$; $\vec{J}_{sL} = \frac{1}{2}L_\sigma^\dagger \vec{\sigma}_{\sigma\sigma'} L_{\sigma'}$ are the ferromagnetic ($q = 0$) spin currents of right- and left-moving electrons respectively, and

$$\vec{n}_s(x) = e^{-i2k_F x_j} \vec{n}_R(x) + e^{+i2k_F x_j} \vec{n}_L(x)$$

where $\vec{n}_R = R_\sigma^\dagger \frac{\vec{\sigma}_{\sigma,\sigma'}}{2} L_{\sigma'}$; $\vec{n}_L = L_\sigma^\dagger \frac{\vec{\sigma}_{\sigma,\sigma'}}{2} R_{\sigma'}$ are the staggered magnetization ($q = 2k_F$) components of the 1DEG.

Due to the incommensurate electron filling, back-scattering interaction terms are irrelevant in the renormalization group (RG) sense, and for our purposes may

be dropped from the Hamiltonian which describe the fixed points. As a result, the spin and charge sectors decouple,

$$H = \int dx [\mathcal{H}_c + \mathcal{H}_{spin}].$$

The charge sector is described by a Gaussian model [5]

$$\mathcal{H}_c = \frac{1}{2} \left[K_c \Pi_c^2(x) + \frac{1}{K_c} v_c (\partial_x \Phi_c)^2 \right].$$

Since in this paper we are not interested in the effects of anomalous 1D exponents ($K_c \neq 1$), we will set $K_c = 1$, unless otherwise explicitly stated. The subsequent analysis and manipulations deal only with the spin sector fields. The Kondo exchange interaction reduces to

$$H_K = J_K \sum_j \vec{\tau}_j \cdot \vec{J}(x_j). \quad (4)$$

B. Order parameters and staggered correlations

Study of the different stable phases of the Kondo-Heisenberg array begins with an analysis of the gapless excitations of the decoupled fixed point. From there, as usual, we sort the phases by determining which of these excitations become gapped, and which remain gapless in the presence of the (Kondo) couplings between the 1DEG and the Heisenberg chain. Since our ultimate goal is to study the coupled system, we need also to consider the character of gapless excitations constructed of composites operators from the two subsystems. An extensive exposition of the order parameters is given in the appendix. Below, we note only the modes which are relevant for a spin gap system.

In the spin gap phases, only spin-0 modes may be gapless. Thus, we focus our investigation on singlet pairing modes (charge- $2e$, spin-0) and CDW modes (charge-0, spin-0). The corresponding usual 1DEG order parameters are:

$$\mathcal{O}_{SP} = \frac{1}{\sqrt{2}} \left(R_\uparrow^\dagger L_\downarrow^\dagger + L_\uparrow^\dagger R_\downarrow^\dagger \right) \quad (5)$$

$$\mathcal{O}_{CDW} = \frac{1}{2} \left[\left(R_\uparrow^\dagger L_\uparrow + R_\downarrow^\dagger L_\downarrow \right) + \text{h.c.} \right]. \quad (6)$$

Modes of *composite* nature are: A composite odd-parity singlet pairing

$$\mathcal{O}_{c-SP} = -i \left[R_\alpha^\dagger (\vec{\sigma}\sigma_2)_{\alpha\beta} L_\beta^\dagger \right] \cdot \vec{\tau}, \quad (7)$$

and a composite particle-hole mode, $\mathcal{O}_{c-CDW}$, which will play a central role in the ensuing discussion

$$\mathcal{O}_{c-CDW} = \vec{n}_{1DEG} \cdot \vec{\tau}. \quad (8)$$

Upon evaluating the corresponding correlation functions $\chi_i(x, x') = \langle \mathcal{O}_i(x) \mathcal{O}_i(x') \rangle$, we find gapless modes with power law correlations of the form.

$$\chi_i(x_j - x_{j'}) = (-1)^{(j-j')} \chi_0(x_j - x_{j'}), \quad (9)$$

where $\chi_0 \sim x^{-\alpha_i}$. The staggering factor $(-1)^j$ in the correlation functions (9) is effectively modulating the usual power law correlations by the reciprocal lattice vector, $\frac{\pi}{b}$, of the spin chain $\{\tau_j\}$. As a result, the gapless modes are found in unusual finite momentum values: The singlet pairing are with momentum $\frac{\pi}{b}$ (and there is no $k = 0$ singlet pairing with charge $2e$), and the gapless CDW modes are at momentum

$$2k_F^* = 2k_F + \frac{\pi}{b} \quad (10)$$

(and not at $2k_F$ as CDW in free 1DEG). These are the *defining characteristics of a "staggered liquid"*.

Insight into the gapless modes properties is gained by considering the so called η -pairing modes at momentum $\pm 2k_F$,

$$\begin{aligned} \eta_R &= R_\uparrow^\dagger R_\downarrow^\dagger \\ \eta_L &= L_\uparrow^\dagger L_\downarrow^\dagger \end{aligned} \quad (11)$$

corresponding to right and left going singlet pairs. In a bosonization representation (Appendix-A) it is easy to see that the η -pairing operators depend only on the 1DEG charge sector fields. The charge sector is unaffected by the relevant part of the Kondo and Heisenberg interactions in all the zero temperature fixed point. Therefore, the gapless η -pairing modes always exist and carry momentum $2k_F$ as in free 1DEG. It is instructive to define operators

$$\begin{aligned} \eta^{even} &\equiv \frac{1}{\sqrt{2}} (\eta_R + \eta_L) \\ \eta^{odd} &\equiv \frac{1}{\sqrt{2}} (\eta_R - \eta_L). \end{aligned} \quad (12)$$

(thought in themselves they do not carry a well defined momentum quantum number). We found that an interdependence of the gapless modes is established by the following operator identities;

$$\mathcal{O}_{SP} = [\mathcal{O}_{CDW}, \eta^{even}] \quad (13)$$

$$0 = [\mathcal{O}_{CDW}, \eta^{odd}] \quad (14)$$

$$0 = [\mathcal{O}_{c-CDW}, \eta^{even}] \quad (15)$$

$$\mathcal{O}_{c-SP} = [\mathcal{O}_{c-CDW}, \eta^{odd}]. \quad (16)$$

Hence, the *gapless wavenumbers of CDW and pairing operators are always connected by momentum $2k_F$* .

C. Main results: Staggered liquids fixed points

For the purpose of characterizing fixed points, the issue of counting gapless modes requires clarification. Since the η -pairing modes are gapless in all cases were the charge sector is gapless (i.e., at all the fixed points of the Kondo-Heisenberg lattice model at incommensurate filling), the interdependence of modes (given in equations 13,16) implies that formally only the CDW modes need to be counted, while the pairing modes $\mathcal{O}_{SP}$ and $\mathcal{O}_{c-SP}$ are redundantly derived from combinations of CDW and η -pairing operators. In spite of that, since common discussions in the literature are done in terms of the usual pairing order parameters $\mathcal{O}_{SP}$ and $\mathcal{O}_{c-SP}$, we will list them in our tables below.

We have found four distinct fixed points associated with different parameter values:

1. $J_K \ll J_H \ll E_F$; A spin gap phase at weak-intermediate coupling [2].
2. $J_K \gtrsim E_F \gg J_H$; A spin gap "Toulouse point" phase [1] at intermediate coupling.
3. $J_K \gg E_F \gg J_H$; A gapless *staggered* Luttinger liquid phase at strong coupling.
4. $J_K \gg E_F \gg J_H$; A spin gap *staggered* BCS phase at strong coupling, with additional weak attractive charge interactions.

We comment that all the fixed point Hamiltonians (associated with the above noted phases) which we derived are in fact spin rotation invariant, even though the bare interaction parameters were in some cases breaking spin rotation invariance. It is an example of the possibility that the ultimate zero temperature fixed point can posses higher symmetry than the original microscopic model. Yet, we emphasize again that such issues do not affect the validity of our analysis for cataloging the fixed points of the most general microscopic Kondo-Heisenberg model (with or without spin rotation invariance).

In the tables below, we characterize the above noted fixed points in terms of momentum quantum number of their gapless CDW and pairing modes ("X" signifies that the particular mode is gapped).

Spin gap phases fixed points:

	$\mathcal{O}_{CDW}$	$\mathcal{O}_{SP}$	$\mathcal{O}_{c-CDW}$	$\mathcal{O}_{c-SP}$
weak coupling	X	X	$2k_F^*$	$\frac{\pi}{b}$
Toulouse point	$2k_F^*$	$\frac{\pi}{b}$	$2k_F^*$	$\frac{\pi}{b}$
Staggered BCS	$2k_F^*$	$\frac{\pi}{b}$	X	X

Gapless Luttinger liquid fixed points:

Table-2: Gapless Luttinger liquid phase

	$\mathcal{O}_{CDW}$	$\mathcal{O}_{SP}$	$\mathcal{O}_{c-CDW}$	$\mathcal{O}_{c-SP}$
Staggered LL	$2k_F^*$	$\frac{\pi}{b}$	$2k_F^*$	$\frac{\pi}{b}$

Obviously, the gapless LL is characterized by having also gapless spin density wave (SDW) modes and triplet pairing modes.

Whereas previously catalogued liquid phases of the 1DEG have a gapless charge $2e$ pairing mode at $k = 0$, in all of the above noted phases this mode appears at non-zero wave-vector. Similarly, there is no gapless CDW mode at wavenumber $2k_F$.

III. WEAK COUPLING LIMIT ($J_K \ll J_H$) SPIN GAP FIXED POINT

In the *weak inter-chain coupling limit*

$$J_K \ll J_H, E_F.$$

It is allowed to make *further approximation* by taking the continuum limit also for the Heisenberg spin chain (such approximation is not valid in the opposite limit $J_K \gg J_H$, which is discussed in section-IV). The local spin chain field is then also decomposed into the smooth (ferromagnetic) and staggered (antiferromagnetic) components;

$$\tilde{\tau}_j = [\mathbf{J}_R^\tau(x_j) + \mathbf{J}_L^\tau(x_j)] + (-1)^j \mathbf{n}_\tau(x_j). \quad (17)$$

(Note: we will consistently use the subscripts " τ, s " to distinguish the spin chain fields from the 1DEG fields).

In order to distinguish contributions coming from various interaction terms, we introduce distinct Kondo coupling coefficients for forward scattering (J_f) and mixed interactions (J_m);

$$H_K = J_f (\mathbf{J}_R^\tau + \mathbf{J}_L^\tau) \cdot (\mathbf{J}_R^s + \mathbf{J}_L^s) + J_m (-1)^j \mathbf{n}_\tau \cdot (\mathbf{J}_R^s + \mathbf{J}_L^s) \quad (18)$$

The mixed interaction, of the ferromagnetic 1DEG component with the *staggered impurity component* (i.e., the $J_m (-1)^j \mathbf{n}_\tau \cdot (\mathbf{J}_R + \mathbf{J}_L)$ term) has naive scaling dimension $\frac{3}{2}$, but the oscillating $(-1)^j$ factor, which acts as an effective extra derivative factor (∂_x), renders this term to be perturbatively irrelevant in the renormalization group sense with respect to the free Hamiltonian, H_0^s . The forward current-current interaction, $J_f (\mathbf{J}_{\tau R} + \mathbf{J}_{\tau L}) \cdot (\mathbf{J}_R + \mathbf{J}_L)$, has scaling dimension 2 and is marginal relevant and leads to the opening of a spin gap [2,4]. (The J_m term will prove to be essential for understanding the Toulouse limit solution in section-IV). Therefore, at incommensurate filling in the weak coupling limit, the Kondo-Heisenberg Hamiltonian (1) reduces to

$$H_{weak} = \mathcal{H}^c + \mathcal{H}_0^s + J_f \int dx (\mathbf{J}_R^\tau + \mathbf{J}_L^\tau) \cdot (\mathbf{J}_R^s + \mathbf{J}_L^s) \quad (19)$$

$$\mathcal{H}^c = \frac{1}{2} \left[K \Pi_c^2(x) + \frac{1}{K} v_c (\partial_x \Phi_c)^2 \right]$$

$$\mathcal{H}_0^s = \sum_{\mu=s,\tau} \frac{2\pi v_\mu}{3} (: \mathbf{J}_R^\mu \mathbf{J}_R^\mu : + : \mathbf{J}_L^\mu \mathbf{J}_L^\mu :)$$

where v_τ, v_s are the spin wave velocities of the Heisenberg chain and 1DEG respectively ($v_\tau = \pi J_H/2$). For a detailed derivation of the gapless modes of model (19), we refer the reader to our paper [2]. The end results are quoted in the first line of table-1. It is remarkable that *only* composite modes are gapless.

IV. TOULOUSE LIMIT ($J_H \ll J_K \sim E_F$) SPIN GAP FIXED POINT

In the limit

$$J_H \ll J_K \sim E_F$$

the intra-chain interaction, J_H , is small compared with the interchain interaction, J_K , and it is *incorrect* to take the continuum limit for the spin chain prior to accounting for the effect of the interaction J_K . For simplicity, since $J_H \ll J_K$, we will first take the limit $J_H = 0$. (We shall find that bringing back $J_H \ll J_K$ is an irrelevant perturbation, in the renormalization group sense, due to the spin gap of "Toulouse fixed point" phase). Thus, we model the local spins as initially independent, and *leave the Kondo interaction in its discrete form*.

$$H = H_0^{1DEG} + 2J_K \sum_j \tau_j \cdot \psi_\alpha^\dagger(x_j) \frac{\sigma_{\alpha\beta}}{2} \psi_\beta(x_j) \quad (20)$$

In this limit, effective interaction and coherence between the local spins will come about explicitly mediated by the itinerant 1DEG (i.e., in a kind of RKKY which is *not* introduced by hand to the model as J_H).

Below, we review and discuss the "Toulouse point" derivation and results of [1]. For the purpose of calculating correlation functions, we bosonize the 1DEG fermionic fields [5];

$$L_\sigma(x) = \frac{F_\sigma}{\sqrt{2\pi a}} e^{-i\sqrt{\pi}[\theta_\sigma(x) + \phi_\sigma(x)]}$$

$$R_\sigma(x) = \frac{F_\sigma}{\sqrt{2\pi a}} e^{-i\sqrt{\pi}[\theta_\sigma(x) - \phi_\sigma(x)]}$$

Where $\theta_\sigma(x) = \int_{-\infty}^x dx' \Pi_\sigma(x')$, and $[\Pi_\sigma(x'), \phi_\sigma(x)] = -i\delta(x' - x)$, $\sigma = \uparrow, \downarrow$. The anticommuting Klein factors, $\{F_\sigma, F_{\sigma'}\} = \delta_{\sigma, \sigma'}$, are needed for the proper anticommutation of fermions with different spin. As commonly done, we re-express the operators in terms of bosonic spin fields $\phi_s(x) = \frac{1}{\sqrt{2}}[\phi_\uparrow - \phi_\downarrow]$, and charge fields

$\phi_c(x) = \frac{1}{\sqrt{2}}[\phi_\uparrow + \phi_\downarrow]$, and correspondingly defined momenta Π_s and Π_c .

The crucial new step which we introduced in [1] is to make a unitary transformation of the fields,

$$U = \exp \left[-i\sqrt{2\pi} \sum_j \tau_j^z \theta_s(x_j) \right], \quad (21)$$

$$U\sqrt{2\pi}(\partial_x \phi_s)U^\dagger = \sqrt{2\pi}(\partial_x \phi_s) - 2\pi \sum_l \tau_l^z \delta(x_l - x) \quad (22)$$

$$U\tau^+ e^{-i\sqrt{2\pi}\theta_s} U^\dagger = \tau^+. \quad (23)$$

$$U \cos \left[\sqrt{2\pi} \phi_s(j) \right] U^\dagger = (-1)^j \cos \left[\sqrt{2\pi} \phi_s(j) \right] \quad (24)$$

In words, going across an impurity, the spin-phase $\sqrt{2\pi}\phi_s$ is shifted by $\pm\pi$. i.e., transformed fields with opposite spins acquires a phase shift of $\delta_\sigma = \pm\frac{\pi}{2}$. It is reminiscent of the unitarity limit scattering we expect from the low energy physics of the single impurity Kondo effect [6]. Therefore, we interpret the unitary transformation as going to a Kondo strong coupling basis.

The resulting transformed Kondo lattice Hamiltonian is given in equation (25),

$$U^\dagger H U = \tilde{H}_0 + \Delta J_z \sqrt{\frac{2}{\pi}} \sum_j \tau_j^z \partial_x \phi_s(x_j) \quad (25)$$

$$+ \frac{J_\perp}{\pi a} \sum_j \tau_j^x (-1)^j \cos[\sqrt{2\pi}\phi_s(j)]$$

$$\tilde{H}_0 = H_0^s + H_0^c - (J_z + \Delta J_z) \frac{1}{b} \sum_j (\tau_j^z)^2 \quad (26)$$

where, $H_0^s = \frac{v_s}{2} \int dx [\Pi_s^2 + (\partial_x \phi_s)^2]$, and

$$\Delta J_z = J_z - \pi v_F. \quad (27)$$

In (25) we have introduced independent interaction coefficient J_z and $J_\perp$ for the Ising and spin-flip parts of the Kondo exchange interaction J_K . Hence, formally we are here examining a generalization of the Kondo-Heisenberg model (1) to non spin-rotation-invariant interactions.

The transformed fields constitute the low energy spectrum of $\tilde{H}_0$ into which part of the interaction energy has been incorporated. The transformed fields are taking advantage of the Ising part of the magnetic Kondo interaction at the cost of kinetic energy (due to twisting of the spin field $\phi_s(x)$). These are originally high energy states of the bare free 1DEG Hamiltonian, H^{1DEG} . For the transformed fields to become the new low energy states due to interactions, it is clear that the Kondo interaction strength needs to be on the order of the 1DEG bandwidth. To this effect, note the shift of the ground-state energy per impurity (irrespective of the existence of a spin gap) in equation (26);

$$\Delta E_j = -(J_z + \Delta J_z) \frac{1}{b} \sum_j (\tau_j^z)^2 \quad (28)$$

$$= -(2J_z - \pi v_F) \frac{1}{4b}.$$

It represents the absorption of a part of the Kondo interaction energy, $-\frac{2J_z}{4b}$ (equal to the gain from forming an *Ising singlet*) into the transformed free field Hamiltonian (26), at the cost of kinetic energy $+\frac{\pi v_F}{4b}$. Hence, for strong enough interactions the transformed free fields have lower energy than the bare 1DEG free fields, and therefore determine the low frequency correlations of various order parameters. Thus, the Toulouse point solution is an outcome of finite "strong enough" interactions and cannot be reached by perturbative methods about the non-interacting basis.

For a special value of the coupling constants,

$$J_z = \pi v_F \implies \Delta J_z = 0 \quad (29)$$

(the "Toulouse point"), we are left with an exactly solvable fixed point Hamiltonian [1],

$$\tilde{H}^* = H_0^c + H_0^s + \frac{J_\perp}{\pi a} \sum_j \tau_j^x (-1)^j \cos[\sqrt{2\pi}\phi_s(j)]. \quad (30)$$

The spin part of the fixed point Hamiltonian has a discrete sine-Gordon form, and therefore, a spin gap. The transformed spin fields which develop an expectation value are $\langle \tau_j^x (-1)^j \rangle \neq 0$ and $\langle \cos[\sqrt{2\pi}\phi_s(j)] \rangle \neq 0$. In calculating correlation functions, it is important to remember the effect of the unitary transformations which lead to

$$\langle \cos[\sqrt{2\pi}\phi_s(x)] \cos[\sqrt{2\pi}\phi_s(x')] \rangle \sim (-1)^{j-j'}$$

($j(x)$ is defined as the j -impurity site to the left of position x). The bare impurity correlations $\langle \tau_j^x \tau_{j'}^x \rangle$ decays exponentially. However, the transformed impurity spin, $\tilde{\tau}_j^x = U^\dagger \tau_j^x U$, exhibit staggered long-range order at $T = 0$, $\langle \tilde{\tau}_j^x \tilde{\tau}_{j'}^x \rangle = \text{const} \cdot (-1)^{(j-j')}$; This non-local order parameter characterizes the coherent ground state. That is all the information needed for deducing the correlation functions of all order parameters, and thus determine the gapless modes as done in [1] and summarized in the second line of table-1.

We take this opportunity to elaborate on the significance of the fields transformation. The π phase shift of the field $\sqrt{2\pi}\phi_s$ across an impurity site (22), give rise to a staggered coefficient $(-1)^j$ in the Hamiltonian (30) since

$$\exp \left[i2\pi \sum_{l=1}^j \tau_l^z \right] = (-1)^j.$$

Note that the factor $(-1)^j$ is effectively "counting" impurities, and is obtained irrespective of the order of the bare $\{\tau_l^z\}$ themselves (imagine an Ising chain of $\{\tau_l^z\}$, there is a factor $e^{\pm i\pi} = -1$ per impurity). Indeed, the correlation function $\langle \tau_j^z \tau_{j'}^z \rangle$ is short range.

It is interesting to trace back the relevant interaction in the Toulouse fixed point Hamiltonian in terms of the continuum limit of the Heisenberg spin chain (18). Due to the additional $(-1)^j$ phase factor, in the transformed basis, the relevant slowly varying interaction is now $J_m \mathbf{n}_\tau \cdot (\mathbf{J}_R + \mathbf{J}_L)$, while the interaction $J_f (-1)^j (\mathbf{J}_{\tau R} + \mathbf{J}_{\tau L}) \cdot (\mathbf{J}_R + \mathbf{J}_L)$ is now also rapidly oscillating and irrelevant!! Thus, Toulouse fixed point physics originates from the interaction J_m that couples the conduction electrons to the staggered component of the impurity array, an interaction that is relevant only with respect to the transformed fixed point Hamiltonian, $\tilde{H}_0$, and was irrelevant in the untransformed basis. This possibility would be missed in the continuum limit if we had dropped the $J_m (-1)^j \mathbf{n}_\tau \cdot (\mathbf{J}_R + \mathbf{J}_L)$ term at the outset (as is usually done, e.g., in [4]). The perturbative relevance of various interaction terms is changed after a transformation to the "proper" strong coupling basis of fields about which perturbative RG analysis is performed. The notation J_m is not accidental, and it is exactly the one which is responsible for the non-trivial fixed point of the two-impurity Kondo problem [11].

V. STRONGER COUPLING ($J_H \ll E_F \ll J_K$) STAGGERED LUTTINGER LIQUID FIXED POINT

A. Phase transition away from the Toulouse limit

In a previous paper [1], we analyzed the commensurate-incommensurate (C-I) transition in the *charge* sector at the Toulouse point, as a function of the filling factor, and found a phase transition from an insulating phase (with both charge and spin gaps) to a conducting phase with only a spin gap. Here, we are interested only in the case of incommensurate filling (for which there is no charge gap). In this section, we analyze the phase transitions in the *spin* sector by varying the parameter values *away from* the Toulouse point, While maintaining the same incommensurate charge filling factor.

We investigate the *phase transitions within the transformed fields Hamiltonian* (25). The local stability of the Toulouse limit fixed point ($J_z^* = \pi v_F$) is ensured by the existence of a spin-gap. This is all that can be deduced from perturbative renormalization group calculations. Thus, the phase transition can be established only via non-perturbative methods. Below, we determine analytically the finite parameter space region characterized by the Toulouse fixed point solution. i.e., the zero temperature stability of the spin gap to finite deviations $\Delta J_z = (J_z - \pi v_F) > 0$ away from the Toulouse line towards stronger coupling. We find a new electronic gapless phase beyond a finite distance from the Toulouse point.

Treating the transformed impurity spins in self-consistent mean-field approximation, we replace them by

their expectation values in the transformed Hamiltonian;

$$U^\dagger H U \rightarrow H_0^s + H_0^c + \Delta J_z \sqrt{\frac{2}{\pi}} \sum_j \langle \tau_j^z \rangle \partial_x \phi_s(x_j) \quad (31)$$

$$+ \frac{J_\perp}{\pi a} \sum_j \langle (-1)^j \tau_j^x \rangle \cos[\sqrt{2\pi} \phi_s(j)].$$

The *spin sector* of the Hamiltonian (31) has a form familiar from the study of Commensurate-Incommensurate (C-I) transitions;

$$\frac{\tilde{H}^s}{v_s} = \frac{1}{2} \int dx [\Pi_s^2 + (\partial_x \phi_s - \delta)^2] \quad (32)$$

$$+ h \int dx \cos[\beta \phi_s(x)]$$

Where, $\beta = \sqrt{2\pi}$,

$$\delta = \delta_0 \sin(\gamma) = \Delta J_z \frac{c}{a} \sqrt{\frac{2}{\pi}} \langle \tau_j^z \rangle \quad (33)$$

$$h = h_0 \cos(\gamma) = J_\perp |\langle \tau_j^x \rangle| \frac{c}{2\pi a^2 v_s}.$$

where $c = \frac{b}{a}$, and

$$\langle (-1)^j \tau_j^x \rangle = \frac{1}{2} \cos(\gamma) \quad (34)$$

$$\langle \tau_j^z \rangle = \frac{1}{2} \sin(\gamma)$$

The general character of the phase transition in the Hamiltonian (32) is well known [7]: The system remains commensurate until $|\delta|$ exceeds a finite critical value δ^c . Therefore, the *Toulouse limit is proved to be stable over a finite range of parameter space*, $\Delta J_z \neq 0$.

Yet, care should be taken to identify the exact nature of the transition and the character of the ensuing gapless phase. The groundstate of (32) is determined by the field configuration that minimize the energy. As we shall see, the C-I transition in our Hamiltonian (31) is unusual due to the fact that the parameters δ and h are themselves not constants, but instead are dynamic fields which need to be *determined self-consistently by the additional mean-field minimization condition* on $\langle \tau_j^z \rangle$ and $\langle \tau_j^x \rangle$. There are, in principle, three possible ground state solutions for the Hamiltonian (32):

- Phase-1: A uniform spin gap phase, identical to the Toulouse point solution, with no finite gradients of $\partial_x \phi_s(x_j)$ i.e., $\langle \cos[\sqrt{2\pi} \phi_s(j)] \rangle \neq 0$, $\langle (-1)^j \tau_j^x \rangle \neq 0$, $\langle \partial_x \phi_s \rangle = 0$, and hence, also $\langle \tau_j^z \rangle = 0$.
- phase-2: A gapless incommensurate spin "soliton lattice" ground state with periodic step-like kinks in the $\phi_s(x_j)$ field. In such a phase, $\langle \partial_x \phi_s \rangle \neq 0$, but still $\langle \cos[\sqrt{2\pi} \phi_s(j)] \rangle \neq 0$, and both $\langle (-1)^j \tau_j^x \rangle \neq 0$ and $\langle \tau_j^z \rangle \neq 0$.

- Phase-3: A free gapless SDW phase; $\langle \partial_x \phi_s \rangle \neq 0$, $\langle \cos[\sqrt{2\pi}\phi_s(j)] \rangle = 0$. In that phase $\langle \tau_j^x \rangle = 0$ and $\langle \tau_j^z \rangle \neq 0$.

The name "soliton lattice" comes from the classical solution, which has long range periodic order. Quantum fluctuations turn the long range order into power-law correlations, and thus the quantum ground state should properly be termed a soliton liquid. Nevertheless, this does not change the qualitative distinctions (in terms of non-zero expectation values) between the various phases. For simplicity, I will *discuss the phases in classical terms*.

To find the transition points between the phases we need to compare, for a given $\Delta J_z = (J_z - \pi v_F) \neq 0$, the ground state energies of the spin gap phase (phase-1) with the that of the gapless phases. The usual result for commensurate-incommensurate transition, where the parameters h and δ are constant, is that the soliton lattice solution (phase-2) has lower energy than the SDW solution, and transition is second order. This is *not* the case here, due to the fact that the *parameters h and δ are themselves inter-dependent dynamic variables*. Thus, we need to *minimized the ground state energy with respect to both the soliton spacing, l , (as usually done) and also with respect to the mean-field parameter, γ* .

The resulting commensurate-incommensurate transition in the transformed 1D Kondo lattice Hamiltonian (32), is first order. The argument is the Following: Remember that τ_j^z and τ_j^x are non-commuting. Therefore, if there was a second order transition to the soliton lattice phase than at the transition point, $\delta \approx \frac{4}{\pi}\sqrt{h_0}$, both $\delta \sim \langle \tau_j^z \rangle \neq 0$ and $h \sim |\langle \tau_j^x \rangle| \neq 0$ are less by a *finite* amount from their respective maximum value, δ_0 and h_0 . The energy of the soliton lattice at the second order transition is equal to the energy of the commensurate phase with the same value of h , which is always less than the maximum energy of the commensurate phase-1 (for which $h = h_0$ and $\delta = 0$). Thus, we establish that the commensurate-incommensurate transition is necessarily first order.

But, what is the incommensurate phase? There is no closed expression for the soliton lattice energy away from the dilute limit (i.e., far from the putative second order transition). Yet, we can analyze the competition between phase-2 and phase-3 in the dense soliton lattice limit (when the distance between soliton centers is less than the single soliton width). In that limit, the commensurate energy contribution (due to $h \neq 0$) is exponentially small, while the $\partial_x \phi_s$ term contribution is approximately linear in $\delta < \delta_0$. Thus (again in contrast with the usual case of constant coefficients $\delta, h \neq 0$), the dense soliton lattice energy is less favorable than the SDW phase-3, (in which $h = 0$ and $\delta = \delta_0$).

The above argument leads to two possible scenarios: Either there is a sequence of two first order transitions (phase-1 $\rightarrow$ phase-2 $\rightarrow$ phase-3). Or, there is one first order transition (phase-1 $\rightarrow$ phase-3). We conjecture that

the second possibility is the correct one, and hence the phase transition occurs at $\delta_0^{critical} = \sqrt{2h_0}$, i.e.,

$$(\Delta J_z)_{critical} = \sqrt{\frac{J_\perp}{2v_{sa}}} \quad (35)$$

In conclusion, at a finite deviation $(\Delta J_z)_{critical}$ from the Toulouse point towards strong coupling, there is a *first-order commensurate-incommensurate transition in the spin field ϕ_s , in conjunction with transformed impurity spin flop transition from $\{\langle \tau_j^x \rangle \neq 0, \langle \tau_j^z \rangle = 0\}$ to $\{\langle \tau_j^x \rangle = 0, \langle \tau_j^z \rangle \neq 0\}$* . The transition is from the spin gap phase-1, to the gapless SDW phase-3, with no soliton lattice region.

B. Staggered Luttinger liquid - a new strong coupling phase

The transition in the spin sector to the gapless SDW phase leads to a new state which we call "staggered-Luttinger-liquid". The staggered-LL is expressed in terms of the transformed fermion fields, which have composite phase fields,

$$\tilde{R}_\sigma(x) \equiv U R_\sigma(x) U^\dagger = R_\sigma(x) e^{+i2\pi \sum_{x_j < x} \tau_j^z \sigma} \quad (36)$$

$$\tilde{L}_\sigma(x) \equiv U L_\sigma(x) U^\dagger = L_\sigma(x) e^{-i2\pi \sum_{x_j < x} \tau_j^z \sigma} \quad (37)$$

where $\sigma = \pm \frac{1}{2}$ is the electron spin, and τ^z is the impurity operator which can take values $\pm \frac{1}{2}$, (so $2\pi\tau^z\sigma = \pm \frac{\pi}{2}$).

Same as for the Toulouse point, we calculate the correlation functions with respect to the spectrum of the transformed Hamiltonian. All the order parameters which in Bosonic form depend on the ϕ_s field, have *staggered* correlation functions (as defined in (9)) *irrespective of the impurity configuration $\{\tau_j^z\}$* . Since there is no spin gap, there are now also gapless spin density wave (SDW) and triplet pairing modes. In the bosonization representation, both $\cos(\sqrt{2\pi}\phi_s)$ and $\sin(\sqrt{2\pi}\phi_s)$ have power law decay of correlations (with an added staggered factor $(-1)^{j-j'}$).

The τ_j^z order of the transformed impurity array requires further clarification. The inter-impurity interactions generated by integrating out the transformed 1DEG degrees of freedom in the residual Kondo interaction, $\Delta J_z^f \sum_j \tau_j^z \partial_{x_j} \phi_s$, are long ranged (i.e., well beyond nearest neighbor interaction). Honner and Gulacsi [13] suggest that the effective interaction is ferromagnetic, and thus at least conforms with strong coupling calculations [12].

C. staggered-BCS; A third spin gap phase?

It is interesting to investigate what would be the form of a BCS pairing of a composite staggered-LL? i.e.,

we introduce a conventional weak attractive interaction, $U < 0$ (e.g., due to phonons), to the 1DEG Hamiltonian. The singlet pairing take the form

$$\begin{aligned}\tilde{\mathcal{O}}_{SP} &= \frac{1}{\sqrt{2}} [\tilde{L}_\uparrow \tilde{R}_\downarrow + \tilde{R}_\uparrow \tilde{L}_\downarrow] \\ &= (-1)^{j(x)} \frac{1}{\sqrt{2}} [L_\uparrow R_\downarrow + R_\uparrow L_\downarrow] = (-1)^{j(x)} \mathcal{O}_{SP}.\end{aligned}\quad (38)$$

The resulting pair correlation function is staggered (as defined in (9)), with nodes at the Kondo impurity periodicity. It corresponds to a negative Josephson coupling across each Kondo impurity [14]. We stress that the node in the pair correlation function due to negative Josephson coupling is a *node in the pair center-of-mass motion*. It should not be confused with a node in the relative pair state [15]. There is *no* gapless $k = 0$ pairing mode.

On the other hand, *all* the composite modes are now incoherent! In order to see this, note that in the gapless staggered LL phase, the gapless composite pairing mode $\mathcal{O}_{c-SP}$ came from the component $\sin(\sqrt{2\pi}\phi_s) \tau_j^z$ (see eq.51 in the appendix). Due to the singlet pairing interaction $\langle \cos(\sqrt{2\pi}\phi_s) \rangle \neq 0$, and thus the correlation function $\langle \sin(\sqrt{2\pi}\phi_s(x)) \sin(\sqrt{2\pi}\phi_s(x')) \rangle$ is exponentially decaying. Moreover, as in the staggered LL, $\langle \tau_j^z \rangle \neq 0$ and thus the part $(R_\uparrow^\dagger L_\uparrow^\dagger \tau^- - R_\downarrow^\dagger L_\downarrow^\dagger \tau^+)$ of $\mathcal{O}_{c-SP}$ is also exponentially decaying. These results are summarized in line 3 of table-1.

Our analysis suggests a new possibility: An *unconventional* staggered-BCS pairing phase may arise out of a two step process, where the staggered-LL is a precursor to the staggered-BCS phase; First, at a temperature T_{hf} , set by the renormalized Kondo interaction, there is a cross-over to a staggered-LL phase, characterized by the unitarity limit phase shifts. Then, at a much lower temperature, T_c , a *conventional* BCS pairing mechanism (e.g., phonons) leads to the un-conventional finite momentum BCS pairing state. The above demonstrates the importance of considering the cross-over effects, due to strong interactions, prior to the consideration of pairing mechanisms.

VI. CONCLUDING REMARKS

The main results of this paper are: (1) The identification of the staggered liquids family of fixed point, as summarized in tables-1,2. (2) Derivation of the phase transition from a spin gap phase at intermediate coupling to a gapless staggered LL at strong coupling. (3) The commutation relations (13-16) which relate CDW and pairing modes. Below we make some additional comments on our results.

At weak coupling, the Kondo-Heisenberg model consists of a free electron gas coupled to a spin density wave system. One would naturally expect a BCS mechanism leading to a state of $k = 0$ BCS pairing of conduction

electrons mediated by spin waves of the Heisenberg chain. We find it quite surprising that such a state does not materialize at any stable fixed point of the one dimensional problem.

Previous numerical simulations in the strong coupling limit [12] have found that the "dominant" gapless CDW mode (in a gapless strong coupling LL phase) is with "large Fermi sea" wavenumber $2k_F^*$. Pairing modes were never evaluated. Yet, from our commutation relations (13,16) it is imperative that the pairing correlations are staggered!! We comment that, following the analysis in this paper, it is important that numerical simulations will establish the *existence* of both $\mathcal{O}_{CDW}$ and $\mathcal{O}_{c-CDW}$ gapless CDW modes. The pairing modes then follow automatically as we explained.

The numerical simulations were performed in the extreme strong coupling limit on a particular lattice structure for which our analytical methods are not rigorously valid. Therefore, it is important to establish whether the gapless strong coupling LL phase in the numerical simulations is identical to the one which we derived analytically by a phase transition from the Toulouse limit solution [2].

VII. APPENDIX: DISCUSSION OF ORDER PARAMETERS

The study of the different stable phases of the Kondo-Heisenberg array begins with an analysis of the gapless excitations of the decoupled fixed point. From there, as usual, we sort the phases by determining which of these excitations become gapped, and which remain gapless in the presence of the (Kondo) couplings between the 1DEG and the Heisenberg chain. In order to facilitate the readability of the paper, we give below the explicit expressions of various order parameters:

1. Density wave modes

The low energy spin currents of the 1DEG, $\vec{s}(x)$, can be decomposed into two parts;

$$\vec{s}(x) = \vec{J}_s(x) + [\vec{n}_s(x) e^{i2k_F x} + \text{H.c.}] \quad (39)$$

where

$$\vec{J}_s = \sum_{\lambda,\sigma,\sigma'} \psi_{\lambda,\sigma}^\dagger \frac{\vec{\sigma}_{\sigma,\sigma'}}{2} \psi_{\lambda,\sigma'} \quad (40)$$

$$\vec{n}_s = \sum_{\sigma,\sigma'} R_\sigma^\dagger \frac{\vec{\sigma}_{\sigma,\sigma'}}{2} L_{\sigma'} \quad (41)$$

are respectively the $k = 0$ and the $k = 2k_F$ components of the SDW mode (charge-0, spin-1) of the 1DEG. (The index $\lambda = R, L$ correspond to Right/Left going electron fields).

The Heisenberg chain spin current, $\vec{\tau}_j$, may be similarly decomposed into a $k = 0$ part, $\vec{J}_\tau$, and a finite momentum

$k = \frac{\pi}{b}$ part, $(-1)^j \vec{n}_\tau$ (where $\frac{2\pi}{b}$ is the reciprocal lattice vector of the Heisenberg chain);

$$\vec{\tau}_j = \vec{J}_\tau(x_j) + (-1)^j \vec{n}_\tau(x_j) \quad (42)$$

For the density-wave excitations, we count only the number of finite momentum excitations. It follows by symmetry that, for finite momentum, if there is a gapless mode at momentum q than there is also a gapless mode with momentum $-q$. We count them as one mode. To summarize, the gapless spin-1 excitations of the 1DEG and the Heisenberg spin chain, and the operator whose correlation function is most directly sensitive to it are listed in table-A1.

Table-A1: Gapless SDW excitations

operator	wave number
$\vec{n}_s$	$2k_F$
$\vec{n}_\tau$	$\frac{\pi}{b}$

(43)

The incommensurate 1DEG has one CDW excitation (charge-0 spin-0) with momentum, $2k_F$, created by the operator

$$\mathcal{O}_{CDW} = \frac{1}{2} \sum_{\lambda,\sigma} \psi_{\lambda,\sigma}^\dagger \psi_{-\lambda,\sigma} \quad (44)$$

$$\sim e^{+i[\sqrt{2\pi}\phi_c + 2k_F x]} \cos(\sqrt{2\pi}\phi_s) \quad (45)$$

The generalized Luttinger theorem [3] asserts that there must be a gapless CDW mode at $2k_F^* = 2k_F + \frac{\pi}{b}$. It is realized by the existence of composite-CDW [10] order parameters which are formed by combining a spin-1 SDW of the 1DEG with a spin-1 SDW of the Heisenberg chain into a composite singlet $\hat{O}_{c-CDW}$,

$$\mathcal{O}_{c-CDW} = \vec{s} \cdot \vec{\tau} = \vec{n}_R \cdot \tau = \frac{1}{2} (n^+ \tau_j^- + n^- \tau_j^+) + n^z \tau_j^z \quad (46)$$

$$= \vec{J}_s \cdot \vec{J}_\tau + \vec{J}_s \cdot \vec{n}_\tau (-1)^j + [e^{i2k_F x} \vec{n}_s \cdot \vec{J}_\tau + \text{h.c.}] + [e^{i2k_F x} \vec{n}_s \cdot \vec{n}_\tau + \text{h.c.}] (-1)^j. \quad (47)$$

To summarize, the non-interacting two-chain system of a Luttinger liquid and a Heisenberg spin chain has *gapless finite momentum CDW modes at three wave vectors* (table-A2).

Table-A2: Gapless CDW excitations

operator	wave number
$\vec{n}_s \cdot \vec{n}_\tau$	$2k_F + \frac{\pi}{b}$
$\mathcal{O}_{CDW}$	$2k_F$
$\vec{n}_s \cdot \vec{J}_\tau$	$2k_F$
$\vec{J}_s \cdot \vec{n}_\tau$	$\frac{\pi}{b}$

(48)

Note that the composite-CDW excitations at wave vectors $\frac{\pi}{b}$ and $2k_F + \frac{\pi}{b}$ are not independent, since they can be related through a multiplication by the 1DEG $\mathcal{O}_{CDW}$ (which has wave vector $2k_F$). Thus, there are only three independent gapless CDW modes.

2. Singlet pairing modes

The charge- $2e$ singlet pairing modes also require careful consideration. In addition to the usual $k = 0$ BCS even parity singlet pairing,

$$\mathcal{O}_{SP} = \frac{1}{\sqrt{2}} \left[L_{\uparrow}^{\dagger} R_{\downarrow}^{\dagger} + R_{\uparrow}^{\dagger} L_{\downarrow}^{\dagger} \right] \quad (49)$$

$$\sim e^{+i\sqrt{2\pi}\theta_c} \cos\left(\sqrt{2\pi}\phi_s\right)$$

we note also the existence of an η -pairing mode at momentum $\pm 2k_F$,

$$\eta_R = R_{\uparrow}^{\dagger} R_{\downarrow}^{\dagger} \sim e^{+i\sqrt{2\pi}\theta_c} e^{-i[\sqrt{2\pi}\phi_c + 2k_F x]} \quad (50)$$

$$\eta_L = L_{\uparrow}^{\dagger} L_{\downarrow}^{\dagger} \sim e^{+i\sqrt{2\pi}\theta_c} e^{+i[\sqrt{2\pi}\phi_c + 2k_F x]}$$

corresponding to right and left going singlet pairs.

As with the CDW modes, in addition to the singlet pairing modes of the 1DEG, it is necessary to consider the *composite* singlet pairing, $\mathcal{O}_{c-SP}$, (a product of a triplet pairing in the 1DEG with a spin-1 mode of the Heisenberg chain) which turns out to be *odd parity* [9,8],

$$\mathcal{O}_{c-SP} = -i\frac{1}{2} \left(R_{\uparrow}^{\dagger} \vec{\sigma} \sigma_2 L_{\uparrow}^{\dagger} \right) \cdot \vec{\tau} \quad (51)$$

$$= \frac{1}{2} \left[\left(R_{\uparrow}^{\dagger} L_{\uparrow}^{\dagger} \tau_j^- - R_{\downarrow}^{\dagger} L_{\downarrow}^{\dagger} \tau_j^+ \right) \right. \\ \left. - \left(R_{\uparrow}^{\dagger} L_{\downarrow}^{\dagger} + R_{\downarrow}^{\dagger} L_{\uparrow}^{\dagger} \right) \tau_j^z \right]$$

$$\sim e^{+i\sqrt{2\pi}\theta_c} \left[e^{-i\sqrt{2\pi}\theta_s} \tau_{j(x)}^+ + e^{+i\sqrt{2\pi}\theta_s} \tau_{j(x)}^- \right. \\ \left. + 2i \sin\left(\sqrt{2\pi}\phi_s\right) \tau^z \right]$$

(Note: If we do not take the Klein factors carefully into account than the bosonized form of the singlet and triplet composite pairing is erroneously exchanged!). It can be decomposed into two momentum components: a uniform $k = 0$ composite singlet

$$\hat{\mathcal{O}}_{c-SP}^{k=0}(x) = -i\frac{1}{2} \left(R_{\uparrow}^{\dagger} \vec{\sigma} \sigma_2 L_{\uparrow}^{\dagger} \right) \cdot \vec{J}_{\tau} \quad (52)$$

and a $k = \frac{\pi}{b}$, *i.e.* a *staggered* composite singlet

$$\hat{\mathcal{O}}_{c-SP}^{staggered}(x) = -i\frac{1}{2} \left(R_{\uparrow}^{\dagger} \vec{\sigma} \sigma_2 L_{\uparrow}^{\dagger} \right) \cdot \vec{n}_{\tau} (-1)^j \quad (53)$$

The commutation relations (13-16) relate to each gapless CDW mode a corresponding gapless pairing mode. Therefore, formally, only the η -pairing modes need to

be counted. The concomitant “trivial” existence of the usual BCS pairing $\mathcal{O}_{SP}$ and composite pairing $\mathcal{O}_{c-SP}$ mode should be implicitly understood.

The operator $\mathcal{O}_{c-SP}$ is odd under spin inversion operation ($R_{\uparrow}^{\dagger} \leftrightarrow R_{\downarrow}^{\dagger}$, $\tau^- \leftrightarrow \tau^+$, $\tau^z \leftrightarrow -\tau^z$), as expected for a singlet. Note that it's spin inversion parity is odd, even though the conduction electrons part is in triplet pairing. In that sense the order parameter is a composite singlet. The operator is clearly odd under space inversion operation, P (exchanging R and L). The composite singlet operator, $\mathcal{O}_{c-SP}$, can be arrived at by taking the time derivative of the BCS singlet order parameter [9], $\frac{\partial \mathcal{O}_{SP}}{\partial t} \propto [H_K, \mathcal{O}_{SP}] = \mathcal{O}_{c-SP}$, where H_K is the Kondo-Heisenberg Hamiltonian (20). Therefore, $\mathcal{O}_{c-SP}$ is *odd* under time reversal, or alternatively, has only *odd* - w dependence. The corresponding order parameter on a discrete lattice (e.g. on a zigzag ladder) is [?]

$$\mathcal{O}_{c-SP} = -\frac{i}{2} (-1)^j \left(\psi_j^{\dagger} \sigma \sigma_2 \psi_{j+1}^{\dagger} \right) \cdot \tau_j$$

(The factor $(-1)^j$ is needed so that both odd and even j -sites will conform in the continuum limit representation).

There is a qualitative difference between the commutation relation (14) and previous commutation relations of $\mathcal{O}_{c-SP}$ in the literature. As elaborated below, we generated the composite singlet, $\mathcal{O}_{c-SP}$, by a combination of $2k_F^*$ composite particle-hole mode ($\vec{n}_R \cdot \tau$) and *finite momentum* $k = 2k_F$ singlet (η_L pairing):

$$\vec{n}_R = \vec{\mathcal{O}}_{2k_F-SDW} = R_{\alpha}^+ \frac{\vec{\sigma}_{\alpha\beta}}{2} L_{\beta}$$

$$\mathcal{O}_{c-CDW} = \vec{n}_R \cdot \tau = \frac{1}{2} (n^+ \tau_j^- + n^- \tau_j^+) + n^z \tau_j^z$$

$$\mathcal{O}_{c-SP} = [\eta_L, \mathcal{O}_{c-CDW}] \quad (54)$$

Note that the above generation of the composite singlet pairing is different from the usual way in which it is generated [9] using the $\frac{\pi}{b}$ momentum composite particle-hole mode ($\vec{J}_R \cdot \tau$) and $k = 0$ momentum singlet ($\mathcal{O}_{SP}$ pairing):

$$\vec{J}_R = R_{\alpha}^+ \frac{\vec{\sigma}_{\alpha\beta}}{2} R_{\beta}$$

$$\mathcal{O}_{SP} = \frac{1}{\sqrt{2}} \left[R_{\uparrow}^{\dagger} L_{\downarrow}^{\dagger} - R_{\downarrow}^{\dagger} L_{\uparrow}^{\dagger} \right]$$

$$\mathcal{O}_{c-SP} = \left[\mathcal{O}_{SP}, \vec{J}_R \cdot \tau \right] \quad (55)$$

$\vec{J}_R \cdot \tau$ is an interaction term in the Hamiltonian, which develops a non-zero expectation value, $\langle \vec{J}_R \cdot \tau \rangle \neq 0$, in the spin gap phase of the Kondo lattice Hamiltonian. Thus, the relation $\mathcal{O}_{c-SP} = [\mathcal{O}_{SP}, \vec{J}_R \cdot \tau] = [\mathcal{O}_{SP}, H]$ is important for establishing the time reversal symmetry of $\mathcal{O}_{c-SP}$ as determined by the Hamiltonian. The $(\vec{J}_R \cdot \tau)$ operator is *not one of the gapless modes*. In contrast, $\mathcal{O}_{c-CDW} = \vec{n}_R \cdot \tau$ is a gapless mode in the spin gap

phase. Thus, our relation $O_{c-SP} = [\eta_L, O_{c-CDW}]$, is establishing the *inter-dependence of gapless modes* in the spin gap phase.

The commutation relations (??) and (??) indicate that there must be some symmetry difference between the usual CDW (O_{CDW}) mode of the 1DEG and the composite-CDW (O_{c-CDW}) mode, and that the composite-CDW cannot be used in combination with η^{even} to construct a BCS singlet mode, Δ , (as can be done with the usual CDW). Clearly there is no difference in the global symmetry properties of the two CDW modes (this would have been a violation of the generalized Luttinger's theorem). The difference is in a *relative internal symmetry* of the two chain system; a π relative spin rotation around the z -axis of the 1DEG with respect to the Heisenberg spin chain. This effect is best seen from the Bosonized spin field dependence of the operators,

$$\begin{aligned}\Delta &\sim \cos\left(\sqrt{2\pi}\phi_{1s}\right) \\ O_{CDW} &\sim \cos\left(\sqrt{2\pi}\phi_{1s}\right) \\ O_{c-CDW} &\sim \cos\left(\sqrt{2\pi}[\theta_{1s} - \theta_{2s}]\right)\end{aligned}$$

(where subscripts "1" and "2" refer to the 1DEG and the impurity spin chain respectively). A π relative spin rotation around the z -axis is shifting $\sqrt{2\pi}[\theta_{1s} - \theta_{2s}]$ by π and leaving ϕ_{1s} unaffected.. Thus under this operation, which we label $\mathcal{R}_z^{S-rel}(\pi)$,

$$\begin{aligned}\eta &\longrightarrow +\eta \\ \Delta &\longrightarrow +\Delta \\ O_{CDW} &\longrightarrow +O_{CDW} \\ O_{c-CDW} &\longrightarrow -O_{c-CDW}.\end{aligned}\tag{56}$$

From these transformation properties (56) it is clear that the composite-CDW cannot be used in combination with η^{even} to construct a BCS singlet mode, since under $\mathcal{R}_z^{S-rel}(\pi)$, $\Delta \longrightarrow +\Delta$, while $\eta^{even}O_{c-CDW} \longrightarrow -\eta^{even}O_{c-CDW}$. Hence, our final conclusion is that the Toulouse point phase and the weak coupling limit spin gap phase of the Kondo-Heisenberg model are distinct phases (as summarized in table-1).

There is a simple physical interpretation for what is the distinction made by the $\mathcal{R}_z^{S-rel}(\pi)$ symmetry operation: The composite-CDW (O_{c-CDW}) is actually constructed out of two spin-1 SDW modes which are coherently combined into a total spin singlet. Therefore, the mode is sensitive to the coherent relative phases of the spin fields between the 1DEG and the Heisenberg chain, which is probed by the $\mathcal{R}_z^{S-rel}(\pi)$. In contrast, the "pure" CDW mode (O_{CDW}) of the 1DEG is independent of any relative state of the Heisenberg chain.
